

WILEY

A recent **clinical trial** found that **interferon β -1a** (INF) and

glatiramer acetate

(GA), two of the most commonly prescribed drugs for multiple

sclerosis

(MS), provide no

additional clinical benefit

when

taken together

. While findings published today in

[*Annals of Neurology*](#)

, a journal of the American Neurological Association and Child Neurology Society, suggest that taking both INF and GA together was not superior to GA monotherapy in reducing relapse risk; the combination therapy does appear to

reduce new lesion activity

and

total lesion volume

.

The National Institute of Neurological Disorders and Stroke (NINDS) describes MS as a neuroinflammatory disease, which affects the central nervous system by attacking myelin, a substance found in nerve fibers. NINDS estimates that up to 350,000 individuals in the U.S. are diagnosed with MS, which affects twice as many women as men, with most symptoms appearing between the ages of 20 and 40. Experts believe this complex autoimmune disease may be caused by genetic and environmental factors.

“While there are a number of drugs to treat MS, our study is the first to investigate if the concurrent use of two drugs with different modes of action would provide any additional clinical benefit without side effects,” explains lead author Dr. Fred Lublin, Director of the Corinne Goldsmith Dickinson Center for Multiple Sclerosis at Mount Sinai Medical Center in New York. “The CombiRx study was designed to assess whether IFN and GA in combination was more effective than either alone in

reducing relapse of MS.”

The research team enrolled 1,008 participants from 68 sites in this double-blind, randomized, controlled phase III trial. Participants received IFN plus GA (499), IFN alone (250), or GA alone (259), with 30µg IFN administered intramuscularly weekly and/or 20 mg of GA injected daily. The groups were followed for three years to assess if the combination therapy reduced MS relapse rates.

Trial results found that the IFN plus GA combination did not lessen disease progression according to the Expanded Disability Status Scale (a measure of disability caused by MS) or show change in the Multiple Sclerosis Functional Composite (measure used during clinical trials to assess leg, arm, and cognitive function in MS patients) better than the individual agents over a three-year period. The combination therapy and GA alone were significantly better than IFN in reducing relapse risk. MRI findings also

suggested that the IFN plus GA together were better in reducing new lesions (plaques) and total lesion accumulation than either drug alone.

Dr. Lublin concludes, “Combining two of the most commonly prescribed MS therapies did not produce significant clinical benefit, reducing relapse risk, during the three-year study period. We will continue to monitor this group to determine if the combination therapy displays positive results, particularly in reducing lesion activity, beyond the initial trial timeframe.”

In a related editorial, Dr. Stephen L. Hauser, Department of Neurology Chair at University of California, San Francisco and Editor-in-Chief of *Annals* adds, “In the end, CombiRx was essentially a negative study, with the combination therapy doing no better than monotherapy in reducing MS relapse rate over three years. However, the continued follow-up of this group by Dr. Lublin and colleagues provides an opportunity to develop a

comprehensive long-term history of MS—assessing response to first-generation therapies, possibly predicting individual disease trajectories, and understanding of treatment response. CombiRx could emerge as a model for long-term assessment, not only in MS, but across clinical neuroscience.”

This CombiRx study was funded by a grant from the NINDS—a part of the National Institutes of Health.
